We give analytic expressions for image properties of objects seen around point mass lenses embedded in a flat ΛCDM universe. An embedded lens in an otherwise homogeneous universe offers a more realistic representation of the lens’s gravity field and its associated deflection properties than does the conventional linear superposition theory. Embedding reduces the range of the gravitational force acting on passing light beams thus altering all quantities such as deflection angles, amplifications, shears and Einstein ring sizes. Embedding also exhibits the explicit effect of the cosmological constant on these same lensing quantities. In this paper, we present these new results and demonstrate how they can be used. The effects of embedding on image properties, although small, i.e., usually less than a fraction of a percent, have a more pronounced effect on image distortions in weak lensing where the effects can be larger than 10%. Embedding also introduces a negative surface mass density for both weak and strong lensing, a quantity altogether absent in conventional Schwarzschild lensing. In strong lensing, we find only one additional quantity, the potential part of the time delay, which differs from conventional lensing by as much as 4%, in agreement with our previous numerical estimates.

I. INTRODUCTION

Recently, we have investigated the quantitative effect of embedding on gravitational lensing observations by resorting to a mixture of analytic work with a few numerical applications [1–3]. The analytic results for quantities like the bending angle α produced by a point mass were given as functions of two impact variables r0 and φ1 (see Fig. 1). These two parameters are not independent if the source and deflector redshifts are fixed. Because of the nonlinearity of the expressions, we were only able to give an iterative procedure which allowed us to numerically evaluate the conventional minimum impact Schwarzschild coordinate r0 as a function of φ1 [3]. We have since been able to analytically carry out this iterative procedure [see Eq. (A1) in the Appendix] and hence obtain all lensing properties such as position, shear, etc., as functions of the single impact angle φ1. The solution of the embedded lens equation and comparison with classical lensing theory is therefore greatly simplified. Because the dependence of observable quantities on this angle is highly nonlinear, we are not able to eliminate φ1 in favor of r0. Derivations of our current results follow the steps given in Refs. [1–3] which we will not repeat, but we will instead simply present the new results and use them on two examples.

The point mass lens is the simplest lens to use to demonstrate the effects of embedding; however, all lenses will require corrections. An embedded point mass lens is constructed by condensing a comoving sphere of pressureless dust of a standard homogeneous cosmology to a singular point mass m at the sphere’s center, a construction first made by Einstein himself [4–7]. When the cosmology contains a cosmological constant Λ, the gravity field inside the evacuated sphere is described by the Kottler metric [8,9] rather than the Schwarzschild metric. In this paper, we restrict ourselves to a flat background cosmology whose Friedmann-Lemaître-Robertson-Walker (FLRW) metric is

\[ ds^2 = -c^2dT^2 + R(T)^2 [d\chi^2 + \chi^2(d\theta^2 + \sin^2\theta d\phi^2)]. \]  

(1)

The embedded condensation is described by the Kottler or Schwarzschild-de Sitter metric

\[ ds^2 = -\gamma(r)^{-2}c^2dt^2 + \gamma(r)^2dr^2 + r^2(d\theta^2 + \sin^2\theta d\phi^2), \]  

(2)

where \( \gamma^{-1}(r) = \sqrt{1 - \beta^2(r)} \) and \( \beta^2(r) = rs/r + \Lambda rs^2/3 \). The constants rs and \( \Lambda \) are the Schwarzschild radius \( (2Gm/c^2) \) of the condensed mass and the cosmological constant, respectively. By matching the first fundamental forms at the Kotller-FLRW boundary, angles (θ, φ) of Eqs. (1) and (2) are identified, and the expanding Kotller radius \( r_b \) of the void is related to its comoving FLRW boundary \( \chi_b \) by

\[ r_b = R(T)\chi_b. \]  

(3)

By matching the second fundamental forms the comoving FLRW radius, \( \chi_b \) is related to the Schwarzschild radius \( r_s \) of the Kottler condensation by

\[ \gamma^{-1}(r) = 1 - \frac{1}{2c^2} \left( \frac{r}{r_b} \right)^2 (1 - \beta^2(r)). \]  

(4)
FIG. 1. A photon travels left to right entering a Kottler hole at \( r = r_1, \phi = \pi - \phi_1 \) and returns to the FLRW dust at \( r = r_1 + \Delta r, \phi = \phi_1 + \Delta \phi \). The photon’s orbit has been chosen symmetric in Kottler about the point of closest approach \( r = r_0, \phi = \pi/2 \). Due to the cosmological expansion, \( \Delta r > 0 \). The slope of the photon’s comoving trajectory in the \( x-y \) plane is \( \xi_1 \) when incoming and \( \xi_1 + \alpha \) after exiting. The resulting deflection angle as seen by a comoving observer in the FLRW background is \( \alpha \), which is negative by convention. Expressions for \( r_1, \Delta r, \xi_1, \Delta \phi, \) and \( \alpha \) as functions of the two impact parameters, \( r_0 \) and \( \phi_1 \), can be found in Refs. [1–3].

\[
\begin{align*}
  r_s &= \Omega_m H_0^2 c^2 (R_0 \chi_b)^3. \\
  r_d &= \sqrt{r_s + \Lambda r_d^2/3}.
\end{align*}
\]

Here, \( H_0 \) is the familiar Hubble constant, and the cosmological constant \( \Lambda \) is constrained to be the same inside and outside of the Kottler hole.

In the following sections, we will give image locations and image properties of small sources seen through Kottler voids in an otherwise flat FLRW universe (an embedded lens). We assume that the source and deflector are located at fixed FLRW comoving distances \( \chi_s \) and \( \chi_d \) from the observer which correspond to angular diameter distances \( D_s \) and \( D_d \), and redshifts \( 1 + z_s = R_0/R_s \) and \( 1 + z_d = R_0/R_d \), see Fig. 2. These quantities are computed just as if the void did not exist. Any quantity with a subscript “\( d \)” means that it is evaluated at redshift \( z_d \) when the radius of the Universe was \( R_d = R(T_d) = R_0/(1 + z_d) \). We give lensing properties such as the bending angle \( \alpha \) of Eq. (7) which are a series of smaller and smaller terms, sufficient to see both the shielding effect of embedding and the effect of the expansion rate \( \beta_d = v_d/c \) of the void’s Kottler radius \( r_d = R_d \chi_b \) which existed at FLRW time \( T_d \). The expansion rate \( v_d \) is the speed of the expanding void boundary as measured by a stationary Kottler observer at \( r_d \). It is given by evaluating \( \beta(r) \) defined below Eq. (2) at \( r = r_d \).

When expanding quantities such as \( \alpha \) in a series, we have taken parameters \( \beta_d \) and \( \chi_b/\chi_d = r_d/D_d \) (the angular radius of the Kottler hole, see Fig. 2) to be first-order and \( r_d/r_s \) and \( \Delta r_d^2/3 \) to be second-order. In our results, e.g., Eq. (7), we have used a parameter \( \delta \) to keep track of each order. In Table 1, we give values for these and other parameters for two lens masses, \( m = 10^{12} M_\odot \) (a large galaxy) and \( m = 10^{15} M_\odot \) (a rich cluster) both at redshift \( z_d = 0.5 \) in a flat \( \Omega_m = 0.3, \Omega_\Lambda = 0.7 \) universe with \( H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1} \). We refer to these as the galaxy lens and the cluster lens throughout the paper.

Shielding typically causes the most significant embedding effect on images (i.e., the lowest-order effect) and analytically appears as combinations of trigonometric functions of the impact angle \( \phi_1 \) in quantities like the bending angle \( \alpha \) [see the first \( \cos^3 \phi_1 \) term in Eq. (10) below]. This decrease in \( \alpha \) is caused by the shortened

FIG. 2. A photon travels from a source at comoving distance \( \chi_s \) from the observer and then enters a Kottler hole of comoving radius \( \chi_b \) centered at comoving distance \( \chi_d \) from the observer. The photon is deflected by an angle \( \alpha < 0 \) and returns to the FLRW dust on its way to the observer. Because this is a comoving picture, the orbit inside the void is only representative, and because the true orbit inside the void is symmetric about \( \phi = \pi/2 \) (see Fig. 1), the optical axis is rotated clockwise by the angle \( -\rho \) (see Eq. (14) of Ref. [3]).
period a passing photon is influenced by the mass condensation (recall that in conventional lensing the deflecting force has “∞” range). Corrections caused by the presence of Λ first appear in the void’s expansion rate β_d and are typically smaller than shielding corrections (i.e., are higher-order). It was the search for Λ’s effect on light deflections [10–16] which prompted investigations of embedded lensing [1,17–19].

II. THE EMBEDDED LENS EQUATION

In our results, we have introduced an order parameter δ whose value is equal to 1 but whose purpose is to keep track of terms of similar orders as defined in the previous section. For weak lensing impact angles θ_1, the higher the order of δ the smaller the respective terms. For strong lensing, when δ is sufficiently small, not all terms of a given order are of the same magnitude. By using steps developed in Refs. [1–3], we find that to order δ^4, the source and image positions θ_S and θ_I, as functions of the single impact parameter δ_1, can be written as

\[ θ_S = θ_I + \frac{D_{ds}}{D_s} (1 + δ^2 \frac{X_b}{X_d} \sin^2 δ_1 + \frac{Δr_d^2}{3} \cos δ_1 \sin^2 δ_1)
+ \frac{2}{3} β_d \left( 4 \sin^2 δ_1 + 3 \cos δ_1 \log \left( \frac{\tan \frac{δ_1}{2}}{2} \right) \right) + O(δ^5) \]

(6)

(see Fig. 2), where the bending angle is

\[ δ_1 = \frac{X_b}{X_d} \sin δ_1 \left( 1 - β_d \cos δ_1 + \frac{Δr_d^2}{3} \cos δ_1 \sin^2 δ_1 \right) + O(δ^5) \]

(7)

\[ θ_I = δ_1 \frac{X_b}{X_d} \sin θ_1 \left( 1 - β_d \cos δ_1 + \frac{Δr_d^2}{3} \cos δ_1 \sin^2 δ_1 \right) + O(δ^5) \]

(8)

We identify the pair of Eqs. (6) and (8) and above as the embedded lens equation in parametric form. They can be used to obtain image positions and properties just as in conventional lensing theory. The conventional nonembedded lens equation is recovered by keeping only the lowest-order terms in each expression and assuming cos δ_1 → 1 and r_s sin δ_1 → r_0.

Because of the dependence of each δ order on the impact angle δ_1, higher-order terms which contain trigonometric functions like csc δ_1 or cot δ_1 can become comparable in magnitude with the next lower-order terms for sufficiently small values of δ_1. This happens in strong lensing. For example, the embedded Einstein ring size θ_E is found by first finding the value of δ_1 = δ_E which makes θ_S of Eq. (6) vanish (see δ_E values in Table I) and then evaluating θ'_E = θ_E(δ_E) using Eq. (8). For θ_S to vanish, δ and δ^2 terms must cancel. The result is

\[ (θ'_E)^2 = θ_E^2 \cos δ_E^3 \left( 1 + 3 δ β_d \tan δ_E \sin δ_E + O(δ^2) \right) \]

(9)

where θ_E is the conventional Einstein ring radius defined by

\[ θ_E^2 = \frac{2 r_s D_{ds}}{D_s D_s} \]

(10)
As we have found with most strongly lensed image properties, this value differs only slightly from the conventional value. For the Einstein radius, the embedded value differs somewhat more than 0.05% for the cluster lens and 0.005% for the galaxy lens. In Fig. 3, we have used the embedded lens equation to locate primary and secondary images for the cluster lens. Primary and secondary images positions are given by Eq. (8) and correspond, respectively, to impact angles $\tilde{\phi}_+ \approx \tilde{\phi}_-$ (the Einstein impact angle $\Phi_E$ separates the two image domains, i.e., $\tilde{\phi}_- < \Phi_E < \tilde{\phi}_+$). For a given source position $\Theta_S$, primary and secondary image impact angles $\tilde{\phi}_\pm$ are found by solving $\Theta_S(\tilde{\phi}_\pm) = \pm \Theta_S$ [i.e., by inverting Eq. (6)]. The two images are then located at $\pm \theta_i(\tilde{\phi}_\pm)$ [i.e., by using Eq. (8)]. These two values of $\theta_i$ can then be used to determine primary and secondary image properties.

### III. IMAGE PROPERTIES OF THE EMBEDDED LENS

To evaluate standard image properties, the reader only has to compute the azimuthal and radial eigenvalues $(a_\phi, a_r)$ of the image matrix $\partial \Theta_S / \partial \Theta_1$ using Eqs. (6) and (8). We give them in Eqs. (A2) and (A3) of the Appendix. The primary and secondary values for $a_\phi$ and $a_r$ can then be obtained by inverting $\mu$, $\kappa$, $\gamma_s$, and $\epsilon$ (see Refs. [20,21]) by evaluating

$$
\mu^{-1} = a_\phi a_r, \\
\kappa = 1 - \frac{1}{2}(a_\phi + a_r), \\
\gamma_s = \frac{1}{2}(a_r - a_\phi),
$$

![FIG. 3 (color online). Primary and secondary image positions as functions of source position $\Theta_S$ for the cluster lens of Table I. Beyond $\Theta_S \sim 3.4\Theta_E$, the smallness of the secondary image's impact begins to violate the orbit approximation condition $\sin\theta_1 \gg r_s/r_0$.]

The above expressions give image properties for all values of impact angle $\phi_1$ such that the photon's orbit approximation is valid ($\sin^2 \phi_1 \gg r_s/r_d$), but because of the lengths of the resulting expressions, we find it appropriate to make two approximations in the next section, one for weak lensing and one for strong. The effective surface mass density $\kappa$ for the embedded lens is the one property which does not vanish as it does for the conventional Schwarzschild lens and is plotted in Fig. 4 for both weak and strong lensing of the primary cluster image. By a conventional Schwarzschild lens, we mean conventional linear lensing theory applied to a point mass superimposed on a FLRW background. Even for strong lensing by the cluster, the magnitude of $\kappa$ is only $\sim 0.1\%$ of the critical value. For the galaxy lens, a $\kappa$ plot is similar to the cluster plot but is approximately a factor of 10 smaller.

### IV. WEAK AND STRONG APPROXIMATIONS

We found it necessary to keep terms to order $\delta^4$ in expressions such as $a$ and $\theta_1$ to obtain sufficiently accurate results for most strong lensing quantities. Most weak observable quantities do not require such accuracy. By dividing the domain for $\theta_1$ into strong and weak parts, we are able to give shorter expressions for the two eigenvalues $(a_\phi, a_r)$ of Eqs. (A2) and (A3) and hence simpler expressions for $\mu$, $\kappa$, etc. For the strong domain, we take $0.4\Phi_E < \Phi_1 < 5\Phi_E$, and for the weak, $5\Phi_E < \Phi_1 < \pi/2$. The maximum value for $\theta_1$ is approximately the ratio $r_d/D_d$ which from Table I is $\sim 117$ times the Einstein ring radius $\Phi_E$ for the cluster lens and $\sim 37$ times for the galaxy. Strong lensing consequently occurs for $\theta_1$ values up to $5\theta_E$, and weak lensing begins to occur when $\theta_1$ exceeds that value. To obtain shortened expressions for weak lensing, we need only keep terms of order $\delta^2$. This allows us to determine the lowest-order effects of lens shielding
and void expansion (the $\beta_d$ term) on image properties in the weak domain $5\phi_E < \bar{\phi}_1 < \pi/2$. We find that the approximate expressions are accurate to at least 0.1% down to $\bar{\phi}_1 = 5\phi_E$ for the cluster and to at least 0.03% for the galaxy. For weak lensing, Eqs. (A2) and (A3) simplify to

$$
\alpha^\text{weak}_\phi = 1 - \delta \left( \frac{\theta E D_d}{r_d} \right)^2 \csc^2 \bar{\phi}_1 \cos^3 \bar{\phi}_1 \times \{1 + \delta \beta_d \sec \bar{\phi}_1 (2 + \sin^2 \bar{\phi}_1) + O(\delta)\},
$$

$$
\alpha^\text{weak}_r = 1 + \delta \left( \frac{\theta E D_d}{r_d} \right)^2 \csc^2 \bar{\phi}_1 \{ \cos \bar{\phi}_1 (1 + 2\sin^2 \bar{\phi}_1) + \delta \beta_d (2 - \sin^2 \bar{\phi}_1 + 2\sin^4 \bar{\phi}_1) + O(\delta^2) \}. 
$$

From these, the following image properties result:

$$
(\mu^\text{weak})^{-1} = 1 + 3\delta \left( \frac{\theta E D_d}{r_d} \right)^2 \{ \cos \bar{\phi}_1 + \delta \beta_d \sin^2 \bar{\phi}_1 + O(\delta^2) \} - \delta^2 \left( \frac{\theta E D_d}{r_d} \right)^4 \cot^4 \bar{\phi}_1 \{ (1 + 2\sin^2 \bar{\phi}_1) + O(\delta) \},
$$

$$
\kappa^\text{weak} = -\frac{3}{2} \delta \left( \frac{\theta E D_d}{r_d} \right)^2 \{ \cos \bar{\phi}_1 + \delta \beta_d \sin^2 \bar{\phi}_1 + O(\delta) \}.
$$

In Fig. 5, we have compared image shear and ellipticity of the embedded lens images with conventional (non-embedded) Schwarzschild values. The reader can see that beyond $\bar{\phi}_1 \sim 45^\circ$, the embedded lens differs from Schwarzschild by over 10%. This is caused primarily by the shielding of the embedded mass and increases as the transiting light ray’s minimum impact $r_0$ approaches the void boundary. The embedded amplification $\mu$ differs from conventional Schwarzschild by less than 0.2% for the cluster and 0.02% for the galaxy for the weak lensing domain and only increases to 2.5% for the secondary cluster image in the strong lensing limit $\bar{\phi}_1 \rightarrow 0.4\phi_E$.

The galaxy lens's numbers are significantly less, and neither are plotted.

Using the order parameter $\delta$ to track terms of equal importance is problematic for strong lensing. As discussed above for strongly lensed images, small values of $\bar{\phi}_1$ in trigonometric functions like $\csc^2 \bar{\phi}_1$ increase the numerical magnitudes of some of the terms in Eqs. (A2) and (A3). In the following strong lensing approximation, we have kept terms based on their numerical size at the Einstein ring value $\bar{\phi}_1 = \phi_E$, and ordered them using another parameter $\Delta$ whose value is also 1. For the cluster lens, the $\Delta^1$ terms are of numerical order 0.1, $\Delta^2$ terms are of numerical order 0.01.
The potential part of the embedded lens delay, $\Delta T_{\text{SC}}|_p$, as defined in Ref. [2], is given by taking the difference in the following for the primary and secondary images

$$\frac{c \Delta T_{\text{SC}}|_p}{r_s} = 2(1 + z_d)\left[ \log \cot \frac{\tilde{\phi}_1}{2} - \cos \tilde{\phi}_1 \left( 1 + \frac{1}{3} \cos^2 \tilde{\phi}_1 \right) \right] + \delta \beta_s \cos^2 \tilde{\phi}_1 + O(\delta^5).$$

In Fig. 6, we have compared $\Delta T_{\text{SC}}|_p = \Delta T_{\text{primary}} - \Delta T_{\text{secondary}}$ (i.e., the potential part of the time delay) of the cluster lens with the corresponding conventional (nonembedded) Schwarzschild value. The reader can see that there is a 2–4% difference in arrival times between the theories.

V. CONCLUSIONS

This paper is one of a series of investigations of the differences in image properties caused by including the gravitational lens’s mass in the cosmic mean density. We call such a lens an embedded lens. In this paper, we have eliminated one of the two impact parameters previously required to give embedded point mass lensing quantities such as the bending angle $\alpha$ and the lens equation itself. The theory remains more complicated than the conventional lensing theory, but is now much easier to use. The new analytical expressions for image properties agree with the lowest-order results given in Ref. [3]. They can also be compared with the higher-order results in Refs. [1,2] which were given as functions of the two impact parameters $r_0$ and $\tilde{\phi}_1$. To eliminate $r_0$ in our prior results for quantities such as $\alpha(\tilde{\phi}_1, r_0)$ in Eq. (32) of Ref. [1] and obtain results such as Eq. (7) given in this paper, we had to analytically iterate Eq. (17) of Ref. [3] to determine $r_1(\tilde{\phi}_1)$ and then use the orbit equation (11) of Ref. [1] to determine $r_0(\tilde{\phi}_1)$. The result is given in Eq. (A1) of the Appendix for completeness and to allow the reader to eliminate $r_0$ in other quantities of interest.

We have found that with the exception of the potential part of the time delay and the effective surface mass density $\kappa$, strong lensing quantities are only minimally altered by making the lens mass a contributor to the mean mass density of the Universe. Even there, the effect is less than 5% on the time delay for a huge cluster lens, see Fig. 6. For weak lensing, most effects are small; however, shear and image ellipticity begin to differ significantly ($>10\%$, see Fig. 5) for large impact angles $\tilde{\phi}_1 > 45^\circ$. The one quantity that does not vanish in embedded point mass lensing is $\kappa$. It turns out to be negative,
presumably accounting for the missing FLRW mass density in the Kottler void.

All results given here depend on having a flat ($\Omega = 1$) background. Extending them to $\Omega \neq 1$ is clearly possible. We expect that many results will differ trivially from what we have given here. The applicability of all results given here also depends on the lens being sufficiently condensed so as to be approximated by a point mass. The effects of embedding on extended lenses remains to be investigated [24].

To correct for embedding, we have used the SC cosmologies which are commonly criticized for their unrealistic mass distributions, i.e., holes with masses at their centers which abruptly appear in otherwise uniform backgrounds. The abrupt discontinuity which appears in the cheese is certainly an unrealistic representation of the true matter distribution; however, this is primarily an aesthetic complaint. Fortunately, for SC, its purpose is not to represent the geometry and on the optics of transiting light rays. In those two aspects, SC does quite well. The real shortcoming of a simple Swiss-cheese-type embedded lens (a single condensation moving with the Hubble flow) is the absence of any shear at the site of the embedded lens. For such a simple embedded lens, neighboring inhomogeneities can only be distributed so as to produce a homogenized gravity field at the lens site. Consequently, the accuracy of our predictions can be questioned. Stated simply, the shortcoming of our lens model, and with standard SC itself, is that neighboring and distant inhomogeneities produce an homogenized background at the point where the lens inhomogeneity is inserted. We suspect this “average” lens is not representative because it does not account for effects of local shear. We currently do not have a good estimate of how much dehomogenization alters the shielding radius (which is the major source of embedding effects) because there are no simple Einstein solutions which accurately model local distortions. Such distortions can easily be accommodated in conventional lensing theory, but how they would alter the embedding radius is completely unknown. Exact Einstein solutions containing a local shear can be constructed by using hierarchical models built from SC itself. Such a construction will probably be necessary to dependably estimate how the spherical shielding radius $r_d$ is distorted and possibly extended by a local shear and hence how it modifies predictions made here.

APPENDIX

The minimum Kottler radial coordinate $r_0$ as a function of impact angle $\tilde{\phi}_1$ (see Fig. 1) is

$$r_0 = r_d \sin \tilde{\phi}_1 \left[ 1 - \beta_d \delta \cos \tilde{\phi}_1 + \delta^2 \left[ \beta_d \frac{X_h}{X_d} \frac{1}{2} \sin^2 \tilde{\phi}_1 + \frac{r_s}{r_d} \left( \csc^2 \tilde{\phi}_1 - \frac{1}{2} \csc \tilde{\phi}_1 - \frac{5}{4} \frac{1}{4} \sin^2 \tilde{\phi}_1 \right) + \frac{\Lambda r_d^2}{3} \left( 1 - 2 \sin^2 \tilde{\phi}_1 \right) \right]$$

$$+ \delta^4 \left[ - \frac{X_h}{X_d} \frac{5}{4} r_d + 2 \delta \frac{\Lambda r_d^2}{3} \cos \tilde{\phi}_1 \sin^2 \tilde{\phi}_1 + \beta_d \frac{\Lambda r_d^2}{3} \cos \tilde{\phi}_1 \left( 1 + \frac{9}{2} \sin^2 \tilde{\phi}_1 \right) \right]$$

$$+ \frac{r_s}{r_d} \left( 2 \log \left[ \tan \frac{\tilde{\phi}_1}{2} + \cos \tilde{\phi}_1 \left( \frac{5}{3} + \frac{7}{3} \sin^2 \tilde{\phi}_1 \right) \right] \right) + \delta^4 \left[ \left( \frac{\Lambda r_d^2}{3} \right)^2 \left( 1 - 10 \sin^2 \tilde{\phi}_1 + 11 \sin^4 \tilde{\phi}_1 \right) \right]$$

$$+ \left( \frac{r_s}{r_d} \right)^2 \left[ \frac{15}{16} \left( \frac{\pi}{2} - \tilde{\phi}_1 \right) \cot \tilde{\phi}_1 \csc \tilde{\phi}_1 - \cos \tilde{\phi}_1 \log \left[ \tan \frac{\tilde{\phi}_1}{2} \right] - \csc^4 \tilde{\phi}_1 + \frac{17}{16} \csc^2 \tilde{\phi}_1 + \frac{187}{48} \frac{4}{3} \sin^2 \tilde{\phi}_1 + \frac{59}{12} \sin^4 \tilde{\phi}_1 \right]$$

$$+ \beta_d \frac{X_h}{X_d} \frac{1}{8} \left( \frac{\sin^2 \tilde{\phi}_1}{\sin^4 \tilde{\phi}_1} + \frac{\Lambda r_d^2}{3} \left( 3 \sin^2 \tilde{\phi}_1 - 7 \sin^4 \tilde{\phi}_1 \right) + \frac{r_s}{r_d} \left( 1 - \frac{3}{2} \sin^4 \tilde{\phi}_1 \right) \right) - \frac{r_s}{r_d} \frac{\Lambda r_d^2}{3} \left( 4 \cos \tilde{\phi}_1 \log \left[ \tan \frac{\tilde{\phi}_1}{2} \right] \right)$$

$$+ \frac{137}{24} + \frac{103}{12} \sin^2 \tilde{\phi}_1 - \frac{385}{24} \sin^4 \tilde{\phi}_1 + \frac{1}{4} \left( \frac{X_h}{X_d} \right)^2 \left( \frac{r_s}{r_d} + \frac{\Lambda r_d^2}{3} \right) \sin^4 \tilde{\phi}_1 \right] + O(\delta^5). \quad (A1)$$

All quantities such as $\xi_1$, $\Delta \phi$, $\Delta r$, and $\rho$ (see Figs. 1 and 2), previously given as functions of $\tilde{\phi}_1$ and $r_0$ [1–3], can be expressed as functions of the single impact parameter $\tilde{\phi}_1$ using Eq. (A1).

The azimuthal and radial (with respect to the optical axis, see Fig. 2) eigenvalues $(a_\phi, a_r)$ of the lensing matrix $\partial \theta_\phi / \partial \theta_\phi$ to order $\delta^2$ as functions of the impact angle $\tilde{\phi}_1$ and an additional lens-geometry parameter $(\theta_\phi D_d / r_d)^2$ (a term which is of order $\delta$) are

\[ a_\phi = a_r = \frac{1}{2} \left( 1 - \cos \tilde{\phi}_1 \right) \]
\[
\begin{align*}
