

# Modeling starspots

with Dr. John Wisniewski

Presentation by Simon Lowry

Can we look at a lightcurve of KOI-340 with a transiting companion to model the spots on the star's surface?

Key words: Lightcurve, Starspots

# Who cares?

Why does it matter if we can model spots on other stars?

- Compare to Solar activity
- Stellar magnetic fields
- Differential rotation of stellar surface
- Investigate different magnetic activity in different stellar types

## Meet KOI-340, our friendly neighbourhood binary

- ~2,500 lightyears away
- KOI: Kepler Object of Interest
  - Observed by Kepler Spacecraft in 14 Quarters (2009 - 2013)
- KOI-340 is a solar-type primary star with an M-dwarf companion
  - Eclipsing binary
- Orbital period of companion: ~24 days

# An introduction to STSP

Figure taken from Hebb 2020 (draft)

- Inputs:
  - Star properties
  - Planet properties
  - Lightcurve file with columns for time and flux
  - Fixed spots from in-transit
- STSP outputs parameters for added spots to match lightcurve (red line on left)

Basically, I want to turn this:

into this:

to help increase our understanding  
of other stars and exoplanets

# Methodology

What did I do for 8 weeks?

# Download and normalise lightcurves

**12.96 days** Rotational Period of KOI-340

## Filter lightcurves into *out-of-transit* and *in-transit*

Example of an out-of-transit lightcurve

Example of an in-transit lightcurve

- Many more out-of-transit data points
- Influences chi-squared value of STSP's model
- Cannot ignore the in-transit data points
- Need to reduce out-of-transit data

# Spot modeling

The interesting stuff

- Given spots that fit the in-transit data, add spots to fit the out-of-transit modulation

## Using STSP, model lightcurves for one phase of rotation, centred around each transit

- One rotational period
- Model spots across all longitudes
- Spots will be modeled one transit at a time (consecutive transits should show persistent spot activity)
- There are 46 transits in the Kepler data

# Binning out-of-transit data improves the model:

Before binning out-of-transit data points

→ Notice it ignores the in-transit details

After binning out-of-transit data points

→ Fits the entire lightcurve quite neatly

# Find the minimum number of added spots to get good fits for all 46 transits

Quarter 1 Transit 1 (transit 1)

Quarter 3 Transit 2 (transit 8)

Quarter 2 Transit 2 (transit 4)

Quarter 5 Transit 2 (transit 13)

- Spot parameters are not unique
- Degenerate solutions
- Minimum number of added spots
- Large out-of-transit modulation = large spot
- Might be many smaller spots

So what do these models  
look like anyways?

I heard you're  
looking for a  
model? 😏
